THE GLOBAL CLIMATE IN 2015–2019
The Global Climate in 2015–2019 is part of the WMO Statements on Climate providing authoritative information on the state of the climate and impacts. It builds on operational monitoring systems at global, regional and national scales. It has been authored by: Peter Siegmund, lead author (Royal Netherlands Meteorological Institute), Jakob Abermann (University of Graz, Austria), Omar Baddour, Michael Sparrow, Rodica Nitu, Oksana Tarasova (WMO), Pep Canadell (CSIRO Climate Science Centre, Australia), Anny Cazenave (Laboratoire d’Etudes en Géophysique et Océanographie Spatiales, Centre National d’Études Spatiales and Observatoire Midi-Pyrénées, France), Chris Derksen, Lawrence Mudryk, Stephen Howell (Environment and Climate Change Canada), Arthur Garreau (Météo-France), Matthias Huss (ETH Zürich), Kirsten Isensee, Katherina Schoo (IOC-UNESCO), John Kennedy (UK Met Office), Ruth Mottram (Danish Meteorological Institute), Selvaraju Ramasamy (Food and Agriculture Organization of the United Nations), Blair Trewin (Bureau of Meteorology, Australia), Markus Ziese (Deutscher Wetterdienst).

The mention of specific companies or products does not imply that they are endorsed or recommended by WMO in preference to others of a similar nature which are not mentioned or advertised.

The findings, interpretations and conclusions expressed in WMO publications with named authors are those of the authors alone and do not necessarily reflect those of WMO or its Members.
### Key Climate Indicators

#### Global Temperature Rise

- **2015–2019**
  - Warmest five-year period
  - 0.2 °C higher than 2011–2015

- **2016**
  - Is the warmest year on record, over 1 °C higher than pre-industrial period

#### Ocean Acidification

Ocean acidity increasing due to rising CO₂

#### Ocean Warming

In 2018, global ocean heat content reached record levels

#### Greenhouse Gas Concentrations Increase

<table>
<thead>
<tr>

</tr>
<tr>
<td>CH₄</td>
<td>1856</td>
</tr>
<tr>
<td>N₂O</td>
<td>330</td>
</tr>
</tbody>
</table>

#### Cryosphere

- Arctic average summer minimum and winter maximum sea-ice extents were well below the 1981–2010 average every year from 2015 to 2019.
- Antarctic experienced its lowest and second-lowest summer sea-ice extent in 2017 and 2018, respectively.

#### Sea Level Continues to Rise

Global sea level continued to rise

- Ice melt major contributor

#### Extreme Events

- **2017**
  - >2,000 deaths attributed to Hurricane Maria, Puerto Rico and Dominica

- **2015–2019**
  - >11,000 deaths attributed to heatwaves worldwide

- **2017**
  - >US$ 125 billion economic losses attributed to Hurricane Harvey

- **2016**
  - >US$ 16 billion economic losses attributed to the wildfires in California
Foreword

The Global Climate in 2015–2019 differs from the previous ones in two respects:

(a) It covers the period just after the Paris Agreement, adding therefore another dimension to WMO contributions to monitoring the evolution of the state of the climate since the adoption of the Paris Agreement;

(b) It benefits from the new approach recommended in 2017 by experts from various disciplines, including a new structure which segments the content into two strands: physical climate indicators, focusing on a few critical state of the climate indicators, and selected climate impacts drawn from information provided by contributing organizations, including on food security, population displacement, health, environment and socioeconomic development.

The current report aims to give readers a synthesis of the state of the climate and its impacts over the last five years. It captures physical variations of the climate system that transcend interannual variations arising from large-scale natural drivers, such as the El Niño–Southern Oscillation (ENSO) phenomenon, which occurred during this period. Over the period 2015–2019, we note the behavior of key climate indicators on land, in the sea, in the atmosphere and in the cryosphere which are of great concern, due to the sustained changing of the climate system. Some of these observed changes are accelerating, such as sea-level rise resulting from the rapid melting of ice sheets and glaciers and from the thermal expansion of the ocean. Impacts on food security, health and population displacements are other reasons for concern, in particular in developing countries, where climate variability and change exacerbate the effect of other hampering socioeconomic development factors, including conflicts and structurally weak socioeconomic resilience.

These are challenges in light of which governments, local stakeholders, cities and civil society have been repeatedly urged in recent years to make every effort to save our unique planet and seek innovative solutions for a rapid transition to carbon neutrality, while making all possible efforts to achieve the United Nations Sustainable Development Goals.

Finally, this report would not be possible without the collaborative efforts of WMO Members and the contributions of many national and international organizations and institutions and experts from various countries. On behalf of WMO, I thank all the contributors and congratulate the co-authors for their efforts in assisting WMO in maintaining the high scientific standard of this report.

(P. Taalas)
Secretary-General
Executive summary

Compared to the previous five-year assessment period, 2011–2015, the current five-year period, 2015–2019, has seen a continued increase in carbon dioxide (CO₂) emissions and an accelerated increase in atmospheric CO₂ concentration, with the growth rate 18% higher. The increase in the oceanic CO₂ concentration has increased the ocean’s acidity.

The five-year period 2015–2019 is the warmest of any equivalent period on record globally, with a 1.1 °C global temperature increase since the pre-industrial period and a 0.2 °C increase compared to the previous five-year period.

Continuing and accelerated trends have also predominated among other key climate indicators, including an acceleration of rising sea levels, a continued decline in the Arctic sea-ice extent, an abrupt decrease in Antarctic sea ice, continued ice mass loss in the glaciers and the Greenland and Antarctic ice sheets, and the clear downward trend in the northern hemisphere spring snow cover.

More heat is being trapped in the ocean. The year 2019 had the largest ocean heat content values on record measured over the upper 700 meters. Precipitation has increased in some regions and decreased in others. Heatwaves were the deadliest meteorological hazard in the 2015–2019 period, affecting all continents and resulting in new temperature records in many countries accompanied by unprecedented wildfires that occurred in particular in Europe, North America, Australia, the Amazon rainforest, and the Arctic regions.

Among all weather-related hazards, tropical cyclones were associated with the largest economic losses, floods, landslides, and loss and damage. The costliest hazard event was Hurricane Harvey in 2017, which led to an estimated economic loss of more than US$ 125 billion.

Climate-related risks associated with climate variability and change exacerbated food insecurity in many places, in particular Africa, due to the impact of drought, which increased the overall risk of climate-related illness or death. Higher sea-surface temperatures endangered marine life and ecosystems. Higher temperatures threaten to undermine development through adverse impacts on gross domestic product (GDP) in developing countries.
Key findings

GREENHOUSE GASES

CO₂ EMISSIONS AND GHG CONCENTRATIONS INCREASED

CO₂ is responsible for about 66% of the total radiative forcing from long-lived GHGs since pre-industrial time, with methane (CH₄) responsible for about 17% and nitrous oxide (N₂O) for 6%. The global budget of anthropogenic carbon has continued to grow since 2015 due to the increase in CO₂ emissions from the combustion of fossil fuels (coal, oil and gas) and cement production. CO₂ emissions from 2015 to 2019 are estimated to be at least 208 Gt, exceeding the 200 Gt CO₂ emitted during the previous five-year period of 2010–2014. Sinks for CO₂ are distributed across the hemispheres, on land and oceans, but CO₂ fluxes in the tropics (30°S–30°N) are close to carbon neutral due to the CO₂ sink being largely offset by emissions from deforestation. Sinks for CO₂ in the southern hemisphere are dominated by the removal of CO₂ by the oceans, while the stronger sinks in the northern hemisphere have similar contributions from both land and oceans.

The latest analysis of observations from the WMO Global Atmosphere Watch shows that globally averaged surface concentrations calculated from this in-situ network for CO₂, CH₄ and N₂O reached new highs (Figure 1).

Figure 1. Time series of globally averaged concentrations of CO₂ in ppm (left), CH₄ in ppb (middle) and N₂O in ppb (right). Blue lines are monthly mean global averaged concentrations, red lines are five-year running averaged monthly mean concentrations.

TEMPERATURE

GLOBAL TEMPERATURE CONTINUES TO RISE, 2015–2019 IS SET TO BE WARMEST FIVE-YEAR PERIOD

The years 2015 to 2019 were the five warmest years on record. The average global temperature for 2015–2019 was 1.1 ± 0.1 °C warmer than pre-industrial (1850–1900) and is therefore the warmest of any equivalent period on record. It is 0.21 ± 0.08 °C warmer than the average for 2011–2015 (Figure 2). The year 2016 is the warmest on record, and 2019 is likely to be the second warmest.

Continental-average temperatures typically show greater variability than the global mean. Even so, five-year average temperatures for 2015–2019 were nominally warmer than any five-year period prior to 2015 for each of the inhabited continents.
continents (Figure 3). Figure 4 shows a map of temperature anomalies for 2015–2019 relative to the long-term average for 1981–2010.

The global mean land-surface air temperature$^3$ for 2015–2019 was approximately 1.7 °C above pre-industrial and 0.3 °C warmer than 2011–2015. Nearly all land areas were warmer than average, with the exception of small areas of Canada, central Asia and an area of the Antarctic in the Indian Ocean sector. The five-year average temperatures were the highest on record for large areas of the United States including Alaska, eastern parts of South America, most of Europe and the Middle East, northern Eurasia, Australia, and areas of southern and eastern Africa.

The global mean sea-surface temperature for 2015–2019 was approximately 0.83 °C above pre-industrial levels and 0.13 °C warmer than 2011–2015. Over the oceans, below-average sea-surface temperatures were observed to the south of Greenland (one of the few areas globally to have seen long-term cooling), an area off the coast of West Africa, and areas of the Southern Ocean. Other areas were mostly warmer than average. Record warmth was recorded over areas of the north-east Pacific, the western North Atlantic, the western Indian Ocean, and the Tasman Sea, which has seen a number of severe marine heatwaves in the past five years.

---

$^3$ The global temperature assessment is based on five datasets: HadCRUT.4.6.0.0 (UK Met Office Hadley Centre and Climatic Research Unit, University of East Anglia), GISTEMP v4 (National Aeronautics and Space Administration Goddard Institute for Space Studies), NOAAClimateTemp (National Oceanic and Atmospheric Administration (NOAA), National Centers for Environmental Information (NCEI), ERA5 (European Centre for Medium-range Weather Forecasts), and JRA-55 (Japan Meteorological Agency).
Sea level continues to rise as shown by altimeter satellites. The total elevation of the global mean sea level over the altimetry era (since January 1993) has reached 90 mm. Figure 5 shows the altimetry-based global mean sea-level time series for the period 1993–2019. Superimposed to the long-term trend (highlighted by the thin black curve in Figure 5), temporary positive or negative deviations are related to El Niño and La Niña events, for example in 1997/98, 2011, 2015/16. The average rate of rise is estimated to be 3.24 ± 0.3 mm/yr over the 27-year period, but the rate has increased over that time. Over the five-year period 2014–2019, the rate of global mean sea-level rise has amounted to 5 mm/year, which is partly due to the strong El Niño 2015/16 event. According to the Intergovernmental Panel on Climate Change (IPCC, 2019), the average rate of rise for 2006–2015 is 3–4 mm/yr, which is about 2.5 times the rate for 1901–1990 of 1-2 mm/yr.

The observed rate of global mean sea-level rise has increased from 3.04 mm/year during the 10-year period 1997–2006 to 4.36 mm/year during the previous 10-year period 2007–2016 (Figure 6). The sea-level budget for the period 1993–2016 is closed to within 0.3 mm/year. The contribution of land ice melt from the world glaciers and Greenland and Antarctica has increased over time and now dominates the sea-level budget (World Climate Research Programme Sea Level Budget Group, 2018).

The capacity of the ocean to absorb heat is a critical part of the climate system. It is estimated that around 90% of the radiative imbalance associated with anthropogenic climate change is taken up by the oceans. Over the last 15 years, new observation systems, especially the Argo series of floats, have allowed systematic near-global monitoring of ocean heat content. Prior to 2005, sampling was more infrequent and more widely spaced, and uncertainties in ocean heat content estimates are, therefore, much larger.

Ocean heat content has reached new records since 2015. Measured over the layer from the surface to 700 meters depth, the heat content in the years 2015–2019 was higher than 4 The current rate of global mean sea-level rise of 5 mm/year corresponds to a volume of water discharged by the Amazon river in about 3 months.
in any previous year (Figure 7). In the NCEI “Levitus” dataset, the ocean heat content anomaly (recomputed relative to the reference period 1981–2010) for 2019 was $13.9 \times 10^{22}$ J for the 0–700 meter layer, and $19.8 \times 10^{22}$ J for the 0–2000 meter layer, compared with the pre-2015 annual records of $9.4 \times 10^{22}$ J and $14.5 \times 10^{22}$ J, respectively.\(^5\)

**SEAWATER IS BECOMING MORE ACIDIC**

The ocean absorbs around 23% of the annual emissions of anthropogenic CO\(_2\) to the atmosphere, thereby helping to alleviate the impacts of climate change on the planet. The ecological costs to the ocean, however, are high, as the absorbed CO\(_2\) reacts with seawater and changes the acidity of the ocean. This decrease in seawater pH is linked to shifts in other carbonate chemistry parameters, such as the saturation state of aragonite, the main form of calcium carbonate used for the formation of shells and skeletal material. Observations from open ocean sources over the last 20 to 30 years have shown a clear trend of decreasing average pH, caused by increased concentrations of CO\(_2\) in seawater (Figure 8). Trends of ocean acidification in coastal locations are more difficult to assess, due to the highly dynamic, highly variable coastal environment affected by temperature change, freshwater runoff, nutrient influx, biological activity and large ocean oscillations. There has been an overall increase in acidity of 26% since the beginning of the industrial revolution.

**CRYOSPHERE**

**SEA-ICE EXTENT CONTINUES TO DECREASE**

For all years from 2015 to 2019, the Arctic’s average September minimum (summer) sea-ice extent\(^6\) was well below the 1981–2010 average. Average summer sea-ice extent during 2015–2019 was less variable compared to 2011–2015, when the record-low summer sea-ice extent occurred in 2012. The period 2015–2019 was marked by a considerable retreat of the Arctic sea-ice extent towards the central Arctic particularly prominent in the Beaufort and Chukchi Seas. The long-term trend over 1979–2019 indicates that the summer sea-ice extent in the Arctic has declined at a rate of approximately 13% per decade.

---

\(^5\) The current increase rate of the world’s ocean heat content in the 0–2000-meter layer is about $1 \times 10^{22}$ joules/year. This is about 20 times as much as the world’s annual primary energy consumption, which in 2017 was 13.511 million tons of oil equivalent (BP, 2019), or 0.05 $\times 10^{22}$ joules.

\(^6\) Sea-ice extent is defined as the area covered by sea ice that contains an ice concentration of 15% or more.
The Arctic's average March maximum (winter) sea-ice extent has also declined over the 1979–2019 period at a rate of approximately 2.7% per decade. The average winter sea-ice extent was lower for 2015–2019 compared to 2011–2015. For all years from 2015–2019, the average winter sea-ice extent was well below the 1981–2010 mean, and the four lowest records for winter occurred in these five years. The largest retreat of the sea-ice extent for 2015–2019 has occurred in the Barents and Bering Seas.

In Antarctica, a remarkable feature of 2015–2019 for both the February minimum (summer) and September maximum (winter) has been that sea-ice extent values have fallen well below the 1981–2010 average since 2016. This is in considerable contrast to the 2011–2015 period and the longer-term 1979–2019 period which exhibited increasing trends in both seasons. During 2015–2019, the summer sea ice reached its lowest and second lowest extent on record in 2017 and 2018, respectively, with 2018 also being the second lowest winter extent. For most years from 2015–2019, the sea-ice extent retreat has been predominantly located in the Ross Sea in summer and in the Ross and Weddell Seas in winter.

ICE SHEETS CONTINUE LOSING MASS

The Greenland ice sheet has undergone significant changes over recent decades. While the overall ice mass was rather stable between 1981 and 2000, an accelerated loss of ice has been observed since the turn of the millennium. Greenland has in all lost around 3,800 Gt of ice between 1992 and 2018, contributing about 10.6 mm to global mean sea level during this period. Figure 10 gives an indication of the regional distribution of average surface mass balance (SMB) for the reference period 1986–2005 (left), the anomaly of the 2015–2019 period (middle) and 2018–2019 (right).7 While SMB is measured directly in only a few locations around the ice sheet, SMB is shown here calculated from computer models. The reference periods are based on output from a high-resolution regional climate model (HIRHAM5) driven by climate reanalysis on the boundaries, and the most recent year is based on output from a weather forecasting model (HARMONIE-AROME) with full observational data assimilated.

Figure 9. Time series of sea-ice extent anomalies (%) for the Arctic in March and Antarctic in September (maximum ice extent), and for the Arctic in September and Antarctic in February (minimum ice extent), relative to the 1981–2010 mean. Black bars indicate five-year averages. Source: Sea Ice Index, Version 3 (Fetterer et al., 2017).

Figure 10. Average SMB for the reference period 1986–2005 (left), the anomaly for 2015–2019 (middle) and the end-of-season SMB for 2018–2019 (right). Source: DMI/polarportal.dk
Greenland’s margin showed a mass change that was more positive than the 1981–2010 average. This pattern also occurred for the season 2018/19 (right), when only the most south-eastern part of the country ended with a positive SMB anomaly. The other parts of Greenland, including the interior of the ice sheet, showed a notable negative SMB anomaly that is strongly correlated with the exceptional summer heatwave that peaked in Greenland in early August, producing runoff from the ice sheet of up to 11 billion tons per day.8

The amount of ice lost annually from the Antarctic ice sheet increased at least sixfold between 1979 and 2017. The total mass loss from the ice sheet increased from 40 Gt per year in 1979–1990 to 252 Gt per year in 2009–2017. The contribution to sea-level rise from Antarctica averaged 0.36 ± 0.05 mm per year with a cumulative 14.0 ± 2.0 mm since 1979. Most of the ice loss takes place by melting of the ice shelves9 from below, due to incursions of relatively warm ocean water, especially in west Antarctica and to a lesser extent along the peninsula and in east Antarctica.

GLACIERS UNDERGO RECORD MASS LOSS

Variations in glacier mass are mainly affected by summer air temperatures, solid precipitation and solar radiation. Long-term cumulative glacier mass changes are thus a valuable indicator integrating the effects of various components of the global climate system on snow and ice.

For the period 2015–2019, data from the World Glacier Monitoring Service reference glaciers indicate an average specific mass change of −978 mm water equivalent per year. This is more negative than in all other five-year periods since 1950, including the previous five-year period (2011–2015) (Figure 11).

Global mass change estimates require extrapolation of the scattered direct observations to all glaciers. An assessment at the global scale (Zemp et al., 2019) indicates an acceleration of glacier mass loss since 1985 after moderately negative values. Over the last decade, glaciers lost more than 300 Gt per year on average, leading to a contribution to sea-level rise of about 0.8 mm per year.

SPRING SNOW COVER DECREASED

The northern hemisphere spring snow cover is found across high-elevation, subarctic and Arctic land areas. While small reductions are observed in autumn and winter, seasonal snow loss is mostly in May and June. Snow-cover extent trends over 1967–2019 are −3.4 ± 1.2% per decade for May, and −7.0 ± 1.9% per decade for June (Figure 12). Although May and June snow-cover extent in 2017 and 2018 was near or above historical averages, June 2019 saw a return to below average Arctic snow cover. Spring snow extent during 2011–2015 and 2015–2019 was lower than any previous 5-year period in the data record.
The water equivalent of solid precipitation, which is mainly snow in the local winter season, computed as the product of the monthly precipitation total and fraction of solid precipitation is shown in Figure 13. Above-average snowfall was observed in eastern Europe and eastern United States, while Canada received below-average snowfall. Central Europe and southern South America received less than normal snow. Negative anomalies can be caused by less total precipitation and by a lower fraction of snow, which can lead to reduced water availability by snowmelt in the warm season.

A comparison of the most recent five-year period with previous five-year periods (not displayed) shows that nearly all regions where snow occurs received more snow in the most recent period than in the previous ones, which can be explained by natural variability.

**PRECIPITATION**

**PRECIPITATION INCREASES IN SOME PARTS AND DECREASES IN OTHERS**

Precipitation totals for 2015–2019 were compared with different reference periods. Year-to-year variations can counterbalance positive and negative anomalies at a certain place.

A comparison of the last five years, 2015–2019, with the five-year period 2011–2015 shows that the average precipitation totals were higher in the latter period than in the former in large regions in southern South and North America, eastern Europe, parts of tropical Africa and in most of Asia (Figure 14). In contrast, there was less precipitation in large parts of Europe, parts of tropical and southern Africa, the Greater Horn of Africa, northern North America, Central America and the Caribbean.
a large part of South America, the Indian Monsoon region, most parts of Australia, and the Maritime Continent.

Comparing short periods can exaggerate the effects of slowly varying circulation patterns such as the El Niño–Southern Oscillation (ENSO) or the Indian Ocean Dipole (IOD). Therefore, precipitation totals for 2015 to 2019 were compared to observed totals from 1951 to 2010. Large parts of the northern hemisphere received precipitation amounts rated in the wettest 20% (Figure 15). Some regions around the equator in Africa and Asia also received similarly rated totals, as well as the western interior of Australia and southern South America. In contrast, large regions with precipitation totals rated in the driest 20% were found in northern South and North America, southern Central America and the Caribbean, southern and western Africa, the Indian Monsoon region, Europe, and north- and southeast Australia.

EXTREME EVENTS

DEADLY HEATWAVES AND COSTLY TROPICAL CYCLONES

Many of the major impacts of climate are associated with extreme events. These can be short-term events, such as tropical cyclones, or events that can extend over months or years such as droughts. Some extreme events bring substantial loss of life or population displacement, others may have limited casualties but major economic impacts. Figure 16 provides data on mortality and economic losses in the six WMO Regions associated with high-impact weather and climate events during the period 2015–2019. Heatwaves have been the deadliest meteorological hazard in the 2015–2019 period, with

Figure 15. Total precipitation for 2015–2019 expressed as a percentile of the 1951–2010 reference period for areas that would have been in the driest 20% (brown) and wettest 20% (green) of the years during the reference period, with darker shades of brown and green indicating the driest and wettest 10%, respectively. Source: GPCC, Deutscher Wetterdienst, Germany.

Figure 16. Mortality and economic losses associated with extreme weather in the period 2015–2019. The numbers apply to 99 extreme weather events, chosen on the basis of mortality and economic losses. Source: the NCEI Billion-dollar Weather and Climate Disasters list, the EM-DAT International Disaster Database, and the NatCatSERVICE of Munich Re.
wildfires also featuring especially in the Arctic, including Greenland, Alaska and Siberia, and in the Amazon forest. Summer 2019 saw unprecedented wildfires in the Arctic region. In June alone, these fires emitted 50 Mt of CO₂ into the atmosphere. This is more than was released by Arctic fires in the same month for the totality of the period 2010–2018.

The largest economic losses were associated with tropical cyclones. The 2017 Atlantic hurricane season was one of the most devastating on record, with more than US$ 125 billion in losses associated with Hurricane Harvey alone. In the Indian Ocean, in March and April 2019, unprecedented and devastating back-to-back tropical cyclones hit Mozambique.

High impact events from a mortality and economic point of view are described below, with lists of five most prominent events per type. The lists are chosen based on the impact and the geographical representativeness (Table 2).

TROPICAL CYCLONES

Overall, global tropical cyclone activity since 2015 has been close to the satellite-era average. The 2018 season was especially active, with the largest number of tropical cyclones of any year in the twenty-first century; all northern hemisphere basins had above-average activity, with the north-east Pacific having its largest accumulated cyclone energy (ACE) value on record. 2016 and 2017 were slightly below-average seasons globally, with the 2016/17 southern hemisphere season being amongst the least active of the satellite era, but both were active years in individual basins.

FLOODS

While tropical cyclones are responsible for many of the world’s most destructive floods, there have been many other instances of major flooding since 2015. Some of these floods have been relatively long-lived responses to excessive rainfall in tropical regions during the monsoon season, but others have been shorter-term floods, including flash floods associated with intense rainfall over a few hours. Heavy rains have also contributed to major landslides in some parts of the world.

TORNADOES AND OTHER SEVERE LOCAL STORMS

In the last five years, more than 300 deaths and economic losses of US$ 7.6 billion have been recorded globally as being associated with tornadoes, extratropical cyclones and hailstorms. In the United States, where data are updated regularly, overall tornado activity over the last five-year period has been close to average, with the 2017 season having above-average and the 2016 and 2018 seasons below-average numbers. May 2019 had the second-largest number of tornadoes for any month after April 2011, and 2019 as a whole was the most active since 2011.

HEATWAVES

Extreme heat and heatwaves were recorded in many parts of the world during the period 2015–2019. Heatwaves have a particularly high impact on human health and were responsible for the heaviest casualties of any severe weather or climate during the same period.

Figure 17. Ranking of the highest June and July 2019 temperatures in Europe since 1950, where the darker shades of red indicate record-breaking values. Data source: E-OBS. Source: Copernicus Climate Change Service (C3S)/Royal Netherlands Meteorological Institute.
DROUGHT

Droughts have had major impacts, both humanitarian and economic, in numerous parts of the world since 2015. Significant droughts occurred on all inhabited continents (Figure 18 shows rainfall deficiency for Australia), but some of the largest impacts were in Africa, where millions of people required assistance after food shortages, and significant numbers were displaced.

WILDFIRES

While not strictly a weather phenomenon, wildfires are strongly influenced by weather and climate events. Drought substantially increases the risk of wildfire in most forest regions (although it can reduce the risk of grassland fires, due to lack of fuel), with a particularly strong influence on long-lived fires. The three largest economic losses on record from wildfires have all occurred in the last four years. In 2019, there were unprecedented wildfires in the Arctic and widespread fires in the Amazon rainforest, with dramatic environmental impacts. Later in the year, fires of exceptional extent and duration also affected eastern Australia.

COLD EVENTS

Despite higher temperatures overall, there were numerous significant cold events and snowfalls over the last five years. Many of these occurred in North America.

</tr>
</thead>
<tbody>
<tr>
<td>May and June 2015</td>
<td>India; Pakistan – heatwave</td>
<td>2 248 deaths were reported due to the heat in India, and 1 229 in Pakistan.</td>
</tr>
<tr>
<td>Summer 2015/16, South Africa</td>
<td>heatwave</td>
<td>There were numerous heatwaves in South Africa during the 2015/16 summer. Pretoria broke its previous record high temperature on three separate occasions.</td>
</tr>
<tr>
<td>Summer 2015 and 2018, Europe</td>
<td>heatwaves</td>
<td>In France 3 275 and 1 500 excess deaths were attributed to the heat in 2015 and 2018, respectively.</td>
</tr>
<tr>
<td>Summer 2018/19, Australia</td>
<td>heatwave</td>
<td>Hottest summer on record for Australia. There were also significant heatwaves in the 2016/17 and 2017/18 summers, especially in New South Wales, and in December 2019, which included the hottest area-averaged day on record for Australia.</td>
</tr>
<tr>
<td>June–July 2019, Europe</td>
<td>heatwave</td>
<td>Two major long and extended heatwaves recorded in Europe in June–July 2019 with national records broken in many countries. In southern France, a national record for any month of 46.0 °C was observed, and national records were also set in Germany, Belgium, the Netherlands, Luxembourg and the United Kingdom. The heat dome spread northwards through Scandinavia and towards Greenland where it accelerated the already above-average rate of ice melt. Over 2 400 excess deaths were reported in France, Belgium and the Netherlands.</td>
</tr>
</tbody>

### Drought

#### 2015/16, Northwest South America; Central America; Caribbean – drought
Drought associated with the 2015/16 El Niño affected many parts of northern South America, Central America and the Caribbean. Rainfall averaged across the Amazon basin in Brazil in 2016 was the lowest on record.

#### 2015–2018, Africa – drought
Severely depleted water supply storages occurred in Cape Province of South Africa, leading to Cape Town to potentially run out of water during 2018. This followed severe drought in many parts of southern Africa in 2015 and 2016, following poor rainy seasons in 2014–2015 and 2015–2016. In east Africa in 2016–2017, 6.7 million people in Somalia were experiencing food insecurity at the drought’s peak, decreasing to 5.4 million by the end of 2017 as conditions eased.

#### 2017–2019, Australia (mostly eastern) – drought
There were significant agricultural losses, as well as large-scale fish deaths after the Darling River ceased to flow. Rainfall for the three-year period for New South Wales and in the Murray-Darling Basin was about 10% below previous record lows.

#### October 2017 – March 2018, northern Argentina; Uruguay – drought
There were heavy losses to summer crops with agricultural losses estimated at US$ 5.9 billion.

#### 2018, Europe (northern and central) – drought
There were heavy agricultural losses across numerous countries, and low flows in the Rhine severely disrupted river transport, causing significant economic losses.

### Wildfire

#### 2015, Indonesia – wildfire
Drought led to extensive wildfires in Indonesia in the second half of 2015. 2.6 million hectares were reported to have burned. 34 deaths were directly attributed to the fires.

#### May 2016, Canada (Alberta) – wildfire
A wildfire caused major damage in Fort McMurray, Alberta, in May. Insured losses exceeded US$ 3 billion with indirect losses of several billion dollars more.

#### July 2018, Greece – wildfire
Major fast-moving wildfires affected the region around Athens, driven by strong winds which reached 124 km/h. At least 99 deaths were reported, the heaviest loss of life in a wildfire globally since 2009.

#### November 2018, USA (California) – wildfire
The town of Paradise was largely destroyed by a fast-moving wildfire. At least 85 lives were lost, and economic losses were estimated at US$ 16.5 billion, the largest on record for a wildfire globally.

#### 2019, eastern Australia – wildfire
Eastern Australia experienced an exceptionally severe and prolonged wildfire season in late 2019, with major fires first breaking out in early September and continuing into early 2020. More than 10 million hectares were burnt in an area extending from southern Queensland to eastern Victoria, while other major fires occurred in South Australia. At least 33 deaths were reported, and preliminary assessments indicate economic losses of several billion dollars.
Cold event

<table>
<thead>
<tr>
<th>Event Date</th>
<th>Location</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>February 2015, eastern USA and Canada</td>
<td>-</td>
<td>Persistent cold in the north-east United States and eastern Canada. It was the second coldest February on record for the north-east region of the United States.</td>
</tr>
<tr>
<td>January 2016, East Asia</td>
<td>-</td>
<td>In late January, abnormally low temperatures extended south from eastern China as far south as Thailand. Guangzhou experienced its first snow since 1967 and Nanning its first since 1983.</td>
</tr>
<tr>
<td>July 2017, Argentina</td>
<td>-</td>
<td>Temperature at Bariloche, Argentina, fell to −25.4 °C on 16 July, 4.3 °C below the previous lowest on record.</td>
</tr>
<tr>
<td>February–March 2018, Europe</td>
<td>-</td>
<td>Abnormal cold for late winter and early spring extended across much of Europe. Eastern Ireland had its heaviest snowfalls for more than 50 years with totals exceeding 50 cm in places.</td>
</tr>
<tr>
<td>January–February 2019, north-central USA; interior western Canada</td>
<td>-</td>
<td>Persistent very cold conditions in late January and February in the north-central United States and interior western areas of Canada.</td>
</tr>
</tbody>
</table>

ATTRIBUTION OF EXTREME EVENTS

THE LIKELIHOOD OF OCCURRENCE OF HEATWAVES HAS BEEN SIGNIFICANTLY INCREASED BY ANTHROPOGENIC CLIMATE CHANGE

Determining the extent, if any, to which the chance of extreme events occurring has been affected by anthropogenic climate change is an active area of science, with hundreds of papers published in the last five years. Many of these studies appear one to two years after the event, but there is also an increasing interest in attribution of events relatively soon after the event, using already established methods.

According to recently published peer-reviewed studies in the annual supplement to the *Bulletin of the American Meteorological Society*, over the period 2015 to 2018, 76 of the 94 events reported in which anthropogenic influence was assessed show a significant anthropogenic influence on the event’s occurrence, either directly, or indirectly (through, for example, influencing atmospheric circulation patterns that contributed to the event). Attribution studies are also published in other journals and reports.

Almost every study of a significant heatwave since 2015 has found that its probability has been significantly increased by anthropogenic climate change. For example, a study found that the heatwave that affected Japan in July 2018 would have been impossible without human influence. In general, the most clear-cut results are obtained for indicators that cover a large area over a substantial period of time (for example, a national mean monthly temperature), with more uncertainty for results at single locations over periods of a few days.

An increasing number of studies are also finding a human influence on the risk of extreme rainfall events, sometimes in conjunction with other major climate influences such as ENSO. One example is the extreme rainfall in eastern China in June–July 2016, where two studies found that human influence significantly increased the risk of the event, with the signal less clear in a third study.

---

11 Sun and Miao, 2018; Yuan *et al.*, 2018.
12 Zhou *et al.*, 2018.
Some, although not all, droughts also show a direct or indirect human influence, such as the 2016/17 East African drought,\textsuperscript{13} which was strongly influenced by warm sea-surface temperatures in the western Indian Ocean to which human influence contributed.

Very few studies have yet found any human signal in small-scale severe weather events such as thunderstorms and tornadoes, and the limited studies of anthropogenic influence on fire weather, such as the February 2017\textsuperscript{14} event in New South Wales, Australia, have mostly been inconclusive. A notable exception are the weather conditions that led to the wildfires in Eastern Australia in late 2019 and early 2020, whose likelihood has increased by at least 30\% since 1900 as a result of anthropogenic climate change.\textsuperscript{15} While few clear anthropogenic signals have been found in tropical cyclone intensity and frequency, it has been found that human influences have increased the amount of rainfall associated with tropical cyclones. In one notable example, Hurricane Harvey in the Houston area in 2017, a study concluded that human influence increased the amount of rainfall that occurred by about 15\% (8\% to 19\%).\textsuperscript{16}

**HIGHLIGHTS OF PROMINENT CLIMATE-RELATED RISKS**

**RECENT RISE IN FOOD INSECURITY AND GLOBAL HUNGER DUE TO DROUGHT IMPACT**

According to the Food and Agriculture Organization (FAO) annual reports, The State of Food Security and Nutrition in the World, climate variability and extremes are among the key drivers behind the recent rises in global hunger and one of the leading causes of severe food crises (Figure 20). The changing nature of climate variability and extremes is negatively affecting all dimensions of food security (food availability, access, utilization and stability).

\textsuperscript{13} Funk et al., 2019.
\textsuperscript{14} Hope et al., 2017.
\textsuperscript{15} Van Oldenborgh et al., 2020.
\textsuperscript{16} Van Oldenborgh et al., 2017.
The impact of the 2015–2016 El Niño on agricultural vegetation is clearly visible through the frequency of drought conditions in 2015–2017. The map in Figure 21 shows that large areas in Africa, parts of central America, Brazil and the Caribbean, as well as Australia and parts of the Near East experienced a large increase in frequency of drought conditions in 2015–2017 compared to the 14-year average.

The risk of food insecurity and malnutrition is greater nowadays because livelihoods and livelihood assets—especially of the poor—are more exposed and vulnerable to changing climate variability and extremes. In the Horn of Africa, rainfall deficits led to the failure of the 2016 and 2017 rainy seasons and the number of food-insecure people rose significantly in Eastern Africa. In Somalia, more than half of the cropland was affected by drought, and herds had reduced by 40% to 60% due to increased mortality and distress sales. In Malawi, the 2015 floods resulted in severe losses to crops, livestock, fisheries and forestry assets, and production flows. According to the United Nations High Commissioner for Refugees Protection and Return Monitoring Network, some 883,000 new internal displacements were recorded between January and December 2018, with conflict the primary reason for displacement (36%), followed by flooding (32%) and drought (29%). As at September 2018, up to 200,000 of the total estimated 900,000 Rohingya refugees were exposed to these natural hazards.

**THE OVERALL RISK OF CLIMATE-RELATED ILLNESS OR DEATH HAS INCREASED**

Based on WHO data and analysis, the overall risk of heat-related illness or death has climbed steadily since 1980, with around 30% of the world’s population now living in climatic conditions that deliver potentially deadly temperatures at least 20 days a year.

Other climate-related events such as heavy rain and associated floods create favourable conditions for various sorts of epidemic outbreaks. In cholera-endemic countries, an estimated 1.3 billion people are at risk, while in Africa alone about 40 million people live in cholera “hotspots”. WHO has recognized that large cholera outbreaks in eastern and central, and later southern Africa were likely enhanced by El Niño-driven weather conditions, in particular extreme rainfall and floods. Flood events are also often associated with outbreaks of water-borne diseases or those linked to poor sanitation, as was reported in Bangladesh during the August 2017 floods.

**MARINE LIFE AND ECOSYSTEMS ARE BEING THREATENED BY HIGHER SEA-SURFACE TEMPERATURES**

According to IOC-UNESCO, significantly higher sea-surface temperatures, as much as 3 °C above average in some areas, are implicated in dramatic changes to the physical, chemical and biological state of the marine environment, with great impacts on food chains and marine ecosystems, as well as socioeconomically important fisheries. Among the areas significantly affected are the Great Barrier Reef off the east coast of Australia, Pacific island countries such as Fiji and Kiribati, and the Okinawa region of Japan. Coral mortality of up to 50% to 70% has been reported.

IOC-UNESCO also reported that oxygen is declining in the open and coastal oceans, including estuaries and semi-enclosed seas. Since the middle of the last century, there has been an estimated 1%–2% decrease in the global ocean oxygen inventory. Regions with historically low oxygen concentrations are expanding, and new regions are now exhibiting low oxygen conditions. Global warming is expected to contribute to this decrease directly because the solubility of
oxygen decreases in warmer waters, and indirectly through changes in ocean dynamics that reduce ocean ventilation, which is the introduction of oxygen to the ocean interior. 

GROSS DOMESTIC PRODUCT IS FALLING IN DEVELOPING COUNTRIES DUE TO INCREASING TEMPERATURES

The International Monetary Fund found that for a median-and low-income developing country, with an annual average temperature of 25 °C, the effect of a 1 °C increase in temperature leads to a growth decrease of 1.2%. Countries whose economies are projected to be significantly adversely affected by an increase in temperature produced only about 20% of global GDP in 2016; however, they are currently home to nearly 60% of the global population and are projected to be home to more than 75% by the end of the century.
